

NCP1611

Enhanced, High-Efficiency Power Factor Controller

The NCP1611 is designed to drive PFC boost stages based on an innovative *Current Controlled Frequency Fold-back (CCFF)* method. In this mode, the circuit classically operates in *Critical conduction Mode (CrM)* when the inductor current exceeds a programmable value. When the current is below this preset level, the NCP1611 linearly decays the frequency down to about 20 kHz when the current is null. *CCFF* maximizes the efficiency at both nominal and light load. In particular, the stand-by losses are reduced to a minimum.

Like in *FCCrM* controllers, internal circuitry allows near-unity power factor even when the switching frequency is reduced. Housed in a SO-8 package, the circuit also incorporates the features necessary for robust and compact PFC stages, with few external components.

Features

- Near-Unity Power Factor
- Critical Conduction Mode (CrM)
- Current Controlled Frequency Fold-back (CCFF): Low Frequency Operation is Forced at Low Current Levels
- On-time Modulation to Maintain a Proper Current Shaping in CCFF Mode
- Skip Mode Near the Line Zero Crossing
- Fast Line / Load Transient Compensation (Dynamic Response Enhancer)
- Valley Turn on
- High Drive Capability: -500 mA / +800 mA
- V_{CC} Range: from 9.5 V to 35 V
- Low Start-up Consumption
- A Version: Low V_{CC} Start-up Level (10.5 V), B Version: High V_{CC} Start-up level (17.0 V)
- Line Range Detection
- This is a Pb-Free Device

Safety Features

- Non-latching, Over-Voltage Protection
- Brown-Out Detection
- Soft-Start for Smooth Start-up Operation (A version)
- Over Current Limitation
- Disable Protection if the Feedback Pin is Not Connected
- Thermal Shutdown
- Low Duty-Cycle Operation if the Bypass Diode is Shorted
- Open Ground Pin Fault Monitoring

Typical Applications

- PC Power Supplies
- All Off Line Appliances Requiring Power Factor Correction

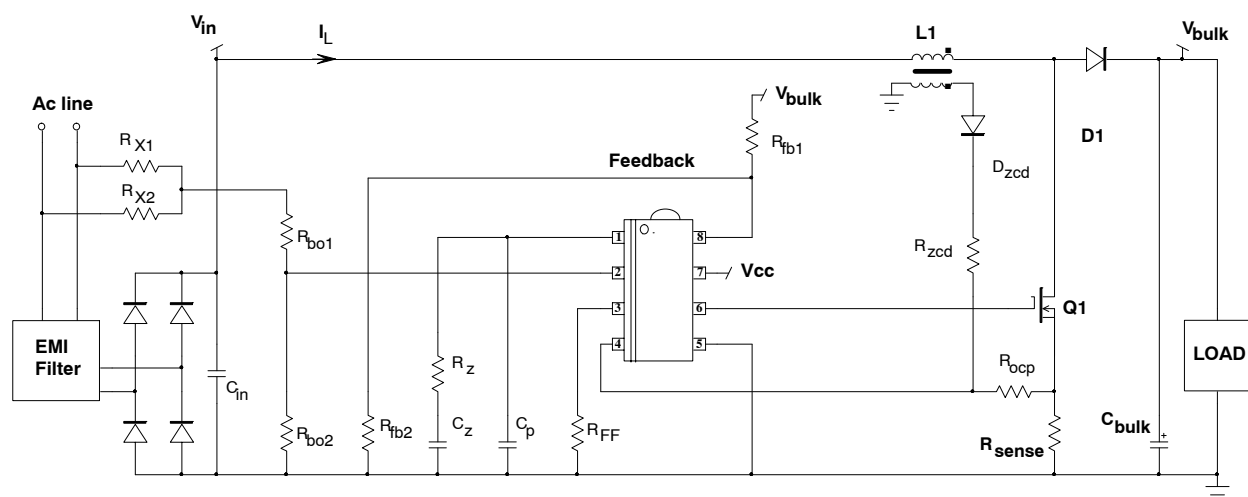

Figure 1.

MAXIMUM RATINGS TABLE

Symbol	Pin	Rating	Value	Unit
V _{CC}	7	Power Supply Input	-0.3, +35	V
V _i	2, 3, 4, 8	Input Voltage (Note 1)	-0.3, +10	V
V _{CONTROL}	1	V _{CONTROL} pin	-0.3, V _{CONTROLMAX} *	V
DRV	6	Driver Votage Driver Current	-0.3, V _{DRV} * -500, +800	V mA
P _D R _{θJA}		Power Dissipation and Thermal Characteristics Maximum Power Dissipation @ T _A = 70°C Thermal Resistance Junction-to-Air	550 145	mW °C/W
T _J		Operating Junction Temperature Range	-40 to +125	°C
T _{Jmax}		Maximum Junction Temperature	150	°C
T _{Smax}		Storage Temperature Range	-65 to 150	°C
T _{Lmax}		Lead Temperature (Soldering, 10s)	300	°C
MSL		Moisture Sensitivity Level	3	-
		ESD Capability, Human Body Model (Note 2)	> 4000	V
		ESD Capability, Machine Model (Note 2)	> 200	V
		ESD Capability, Charged Device Model (Note 2)	2000	V

Stresses exceeding Maximum Ratings may damage the device. Maximum Ratings are stress ratings only. Functional operation above the Recommended Operating Conditions is not implied. Extended exposure to stresses above the Recommended Operating Conditions may affect device reliability.

*"V_{CONTROLMAX}" is the V_{CONTROL} pin clamp voltage. "V_{DRV}" is the DRV clamp voltage (V_{DRVhigh}) if V_{CC} is higher than (V_{DRVhigh}). "V_{DRV}" is V_{CC} unless otherwise noted.

- When the applied voltage exceeds 5 V, these pins sink about $\frac{V_i - 5 \text{ V}}{4 \text{ k}\Omega}$ that is about 1.25 mA if V_i = 10 V.
- This device(s) contains ESD protection and exceeds the following tests:
Human Body Model 2000 V per JEDEC Standard JESD22-A114E
Machine Model Method 200 V per JEDEC Standard JESD22-A115-A
Charged Device Model Method per JEDEC Standard JESD22-C101E.
- This device contains latch-up protection and exceeds 100 mA per JEDEC Standard JESD78.

NCP1611

DETAILED PIN DESCRIPTION

Pin Number	Name	Function
1	V _{CONTROL}	The error amplifier output is available on this pin. The network connected between this pin and ground adjusts the regulation loop bandwidth that is typically set below 20 Hz to achieve high Power Factor ratios. Pin1 is grounded when the circuit is off so that when it starts operation, the power increases slowly to provide a soft-start function.
2	V _{SENSE}	A portion of the instantaneous input voltage is to be applied to pin 2 in order to detect brown-out conditions. If V_{pin2} is lower than 0.9 V for more than 50 ms, the circuit stops pulsing until the pin voltage rises again and exceeds 1.0 V. This pin also detects the line range. By default, the circuit operates the "low-line gain" mode. If V_{pin2} exceeds 2.2 V, the circuit detects a high-line condition and reduces the loop gain by 3. Conversely, if the pin voltage remains lower than 1.7 V for more than 25 ms, the low-line gain is set. Connecting the pin 2 to ground disables the part.
3	FF _{CONTROL}	This pin sources a current representative to the line current. Connect a resistor between pin3 and ground to generate a voltage representative of the line current. When this voltage exceeds the internal 2.5 V reference (V_{REF}), the circuit operates in critical conduction mode. If the pin voltage is below 2.5 V, a dead-time is generated that approximately equates $[83 \mu s \times (1 - (V_{pin3}/V_{REF}))]$. By this means, the circuit forces a longer dead-time when the current is small and a shorter one as the current increases. The circuit skips cycles whenever V_{pin3} is below 0.65 V to prevent the PFC stage from operating near the line zero crossing where the power transfer is particularly inefficient. This does result in a slightly increased distortion of the current. If superior power factor is required, offset pin 3 by more than 0.75 V offset to inhibit the skip function.
4	CS / ZCD	This pin monitors the MOSFET current to limit its maximum current. This pin is also connected to an internal comparator for Zero Current Detection (ZCD). This comparator is designed to monitor a signal from an auxiliary winding and to detect the core reset when this voltage drops to zero. The auxiliary winding voltage is to be applied through a diode to avoid altering the current sense information for the on-time (see application schematic).
5	Ground	Connect this pin to the PFC stage ground.
6	Drive	The high-current capability of the totem pole gate drive ($-0.5/+0.8$ A) makes it suitable to effectively drive high gate charge power MOSFETs.
7	V _{CC}	This pin is the positive supply of the IC. The circuit starts to operate when V_{CC} exceeds 10.5 V (A version, 17.0 V for the B version) and turns off when V_{CC} goes below 9.0 V (typical values). After start-up, the operating range is 9.5 V up to 35 V.
8	Feedback	This pin receives a portion of the PFC output voltage for the regulation and the Dynamic Response Enhancer (DRE) that drastically speeds-up the loop response when the output voltage drops below 95.5% of the desired output level. V_{pin8} is also the input signal for the (non-latching) Over-Voltage (OVP) and Under-Voltage (UVP) comparators. The UVP comparator prevents operation as long as V_{pin8} is lower than 12% of the reference voltage (V_{REF}). A soft OVP comparator gradually reduces the duty-ratio when V_{pin8} exceeds 105% of V_{REF} . If despite of this, the output voltage still increases, the driver is immediately disabled if the output voltage exceeds 107% of the desired level (fast OVP). A 250 nA sink current is built-in to trigger the UVP protection and disable the part if the feedback pin is accidentally open.

DETAILED OPERATING DESCRIPTION

Introduction

The NCP1611 is designed to optimize the efficiency of your PFC stage throughout the load range. In addition, it incorporates protection features for rugged operation. More generally, the NCP1611 is ideal in systems where cost-effectiveness, reliability, low stand-by power and high efficiency are key requirements:

- **Current Controlled Frequency Fold-back:** the NCP1611 is designed to drive PFC boost stages in so-called Current Controlled Frequency Fold-back (CCFF). In this mode, the circuit classically operates in Critical conduction Mode (CrM) when the inductor current exceeds a programmable value. When the current is below this preset level, the NCP1611 linearly reduces the frequency down to about 20 kHz when the current is zero. CCFF maximizes the efficiency at both nominal and light load. In particular, stand-by losses are reduced to a minimum. Similarly to FCCrM controllers, an internal circuitry allows near-unity power factor even when the switching frequency is reduced.
- **Skip Mode:** to further optimize the efficiency, the circuit skips cycles near the line zero crossing when the current is very low. This is to avoid circuit operation when the power transfer is particularly inefficient at the cost of current distortion. When superior power factor is required, this function can be inhibited by offsetting the "FFcontrol" pin by 0.75 V.
- **Low Start-up Current and large V_{CC} range (B version):** The start-up consumption of the circuit is minimized to allow the use of high-impedance start-up resistors to pre-charge the V_{CC} capacitor. Also, the minimum value of the UVLO hysteresis is 6 V to avoid the need for large V_{CC} capacitors and help shorten the start-up time without the need for too dissipative start-up elements. The A version is preferred in applications where the circuit is fed by an external power source (from an auxiliary power supply or from a downstream converter). Its maximum start-up level (11.25 V) is set low enough so that the circuit can be powered from a 12-V rail. After start-up, the high V_{CC} maximum rating allows a large operating range from 9.5 V up to 35 V.
- **Fast Line / Load Transient Compensation (Dynamic Response Enhancer):** since PFC stages exhibit low loop bandwidth, abrupt changes in the load or input voltage (e.g. at start-up) may cause excessive over or under-shoot. This circuit limits possible deviations from the regulation level as follows:
 - The NCP1611 linearly decays the power delivery to zero when the output voltage exceeds 105% of its desired level (soft OVP). If this soft OVP is too smooth and the output continues to rise, the circuit immediately interrupts the power delivery when the output voltage is 107% above its desired level.
 - The NCP1611 dramatically speeds-up the regulation loop when the output voltage goes below 95.5% of its regulation level. This function is enabled only after the PFC stage has started-up to allow normal soft-start operation to occur.
- **Safety Protections:** the NCP1611 permanently monitors the input and output voltages, the MOSFET current and the die temperature to protect the system from possible over-stress making the PFC stage extremely robust and reliable. In addition to the OVP protection, these methods of protection are provided:

- **Maximum Current Limit:** the circuit senses the MOSFET current and turns off the power switch if the set current limit is exceeded. In addition, the circuit enters a low duty-cycle operation mode when the current reaches 150% of the current limit as a result of the inductor saturation or a short of the bypass diode.
- **Under-Voltage Protection:** this circuit turns off when it detects that the output voltage is below 12% of the voltage reference (typically). This feature protects the PFC stage if the ac line is too low or if there is a failure in the feedback network (e.g., bad connection).
- **Brown-Out Detection:** the circuit detects low ac line conditions and stops operation thus protecting the PFC stage from excessive stress.
- **Thermal Shutdown:** an internal thermal circuitry disables the gate drive when the junction

temperature exceeds 150°C (typically). The circuit resumes operation once the temperature drops below approximately 100°C (50°C hysteresis).

- **Output Stage Totem Pole:** the NCP1611 incorporates a –0.5 A / +0.8 A gate driver to efficiently drive most TO220 or TO247 power MOSFETs.

NCP1611 Operation Modes

As mentioned, the NCP1611 PFC controller implements a Current Controlled Frequency Fold-back (CCFF) where:

- The circuit operates in classical Critical conduction Mode (CrM) when the inductor current exceeds a programmable value.
- When the current is below this preset level, the NCP1611 linearly reduces the operating frequency down to about 20 kHz when the current is zero.

Figure 59. CCFF Operation

As illustrated in Figure 59, under high load conditions, the boost stage is operating in CrM but as the load is reduced, the controller enters controlled frequency discontinuous operation.

Figure 60 details the operation. A voltage representative of the input current (“current information”) is generated. If this signal is higher than a 2.5 V internal reference (named “Dead-Time Ramp Threshold” in Figure 60), there is no dead-time and the circuit operates in CrM. If the current information is lower than the 2.5 V threshold, a dead-time is inserted that lasts for the time necessary for the internal

ramp to reach 2.5 V from the current information floor. Hence, the lower the current information is, the longer the dead-time. When the current information is 0.75 V, the dead-time is 50 μs.

To further reduce the losses, the MOSFET turns on is stretched until its drain-source voltage is at its valley. As illustrated in Figure 60, the ramp is synchronized to the drain-source ringing. If the ramp exceeds the 2.5 V threshold while the drain-source voltage is below V_{in} , the ramp is extended until it oscillates above V_{in} so that the drive will turn on at the next valley.

Top: CrM operation when the current information exceeds the preset level during the demagnetization phase

Middle: the circuit re-starts at the next valley if the sum (ramp + current information) exceeds the preset level during the dead-time, while the drain-source voltage is high

Bottom: the sum (ramp + current information) exceeds the preset level while during the dead-time, the drain-source voltage is low. The circuit skips the current valley and re-starts at the following one.

Figure 60. Dead-Time Generation

Current Information Generation

The “FFcontrol” pin sources a current that is representative of the input current. In practice, I_{pin3} is built by multiplying the internal control signal (V_{REGUL} , i.e., the internal signal that controls the on-time) by the sense voltage (pin 4) that is proportional to the input voltage. The

multiplier gain (K_m of Figure 61) is three times less in high-line conditions (that is when the “LLine” signal from the brown-out block is in low state) so that I_{pin3} provides a voltage representative of the input current across resistor R_{FF} placed between pin 3 and ground. Pin 3 voltage is the current information.

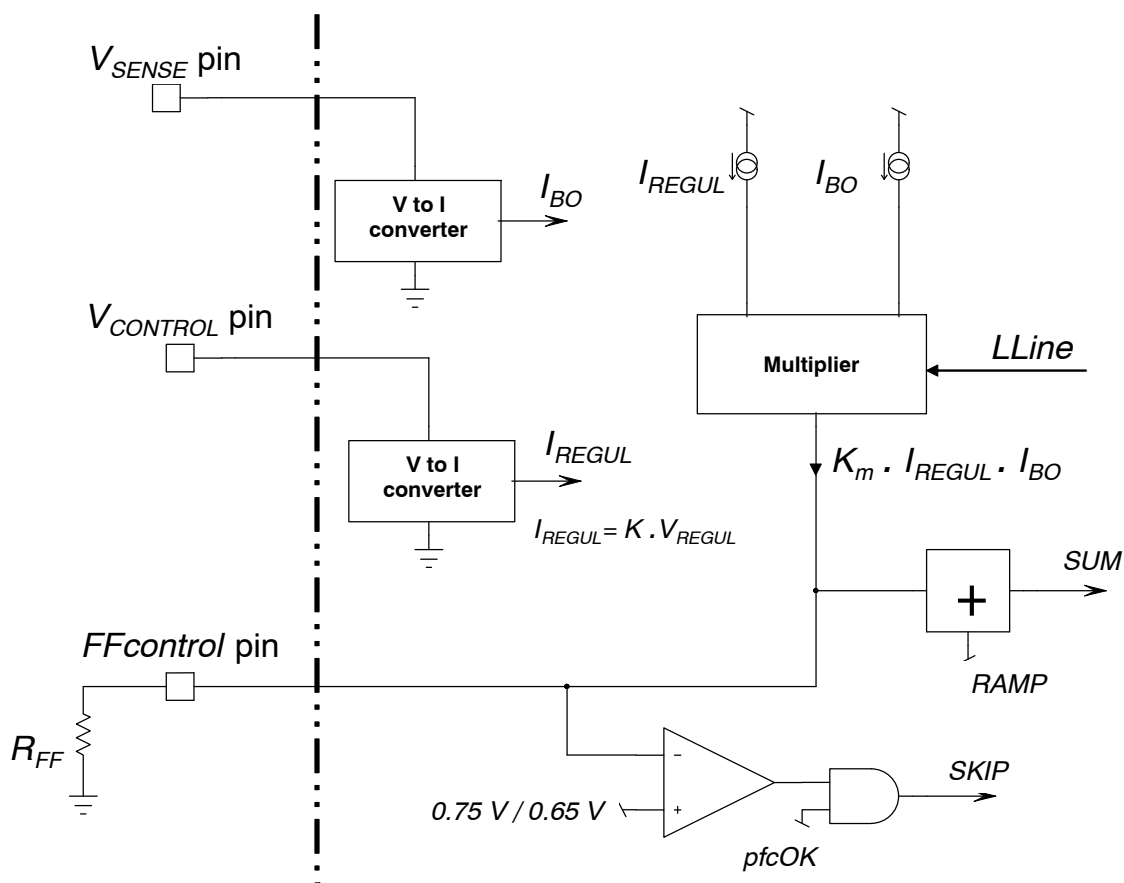

Figure 61. Generation of the Current Information

Skip Mode

As illustrated in Figure 61, the circuit also skips cycles near the line zero crossing where the current is very low. A comparator monitors the pin 3 voltage (“FFcontrol” voltage) and inhibits the drive when V_{pin3} is lower than a 0.65 V internal reference. Switching resumes when V_{pin3} exceeds 0.75 V (0.1 V hysteresis). This inhibits circuit operation when the power transfer is particularly inefficient at the expense of slightly increased current distortion. When superior power factor is needed, this function can be inhibited offsetting the “FFcontrol” pin by 0.75 V. The skip

mode capability is disabled whenever the PFC stage is not in nominal operation (as dictated by the “pfcOK” signal – see block diagram and “pfcOK Internal Signal” Section).

The circuit does not abruptly interrupt the switching when V_{pin3} goes below 0.65 V. Instead, the signal V_{TON} that controls the on-time is gradually decreased by grounding the V_{REGUL} signal applied to the V_{TON} processing block (see Figure 9). Doing so, the on-time smoothly decays to zero in three to four switching periods typically. Figure 62 shows the practical implementation.

NCP1611

Figure 62. CCFF Practical Implementation

CCFF maximizes the efficiency at both nominal and light load. In particular, the stand-by losses are reduced to a minimum. Also, this method avoids that the system stalls between valleys. Instead, the circuit acts so that the PFC

stage transitions from the n valley to $(n + 1)$ valley or vice versa from the n valley to $(n - 1)$ cleanly as illustrated by Figure 63.

Figure 63. Clean Transition Without Hesitation Between Valleys

NCP1611 On-time Modulation

Let's analyze the ac line current absorbed by the PFC boost stage. The initial inductor current at the beginning of each switching cycle is always zero. The coil current ramps

up when the MOSFET is *on*. The slope is (V_{IN}/L) where L is the coil inductance. At the end of the on-time (t_1), the inductor starts to demagnetize. The inductor current ramps down until it reaches zero. The duration of this phase is (t_2).

In some cases, the system enters then the dead-time (t_3) that lasts until the next clock is generated.

One can show that the ac line current is given by:

$$I_{in} = V_{in} \left[\frac{t_1(t_1 + t_2)}{2TL} \right] \quad (\text{eq. 1})$$

Figure 64. PFC Boost Converter (left) and Inductor Current in DCM (right)

The NCP1611 operates in voltage mode. As portrayed by Figure 8, the MOSFET on-time t_1 is controlled by the signal V_{ton} generated by the regulation block and an internal ramp as follows:

$$t_1 = \frac{C_{ramp} \cdot V_{ton}}{I_{ch}} \quad (\text{eq. 2})$$

The charge current is constant at a given input voltage (as mentioned, it is 3 times higher at high line compared to its value at low line). C_{ramp} is an internal capacitor.

The output of the regulation block ($V_{CONTROL}$) is linearly transformed into a signal (V_{REGUL}) varying between 0 and 1 V. (V_{REGUL}) is the voltage that is injected into the PWM section to modulate the MOSFET duty-cycle. The NCP1611 includes some circuitry that processes (V_{REGUL}) to form the signal (V_{ton}) that is used in the PWM section (see Figure 9). (V_{ton}) is modulated in response to the dead-time sensed during the precedent current cycles, that is, for a proper shaping of the ac line current. This modulation leads to:

$$V_{ton} = \frac{T \cdot V_{REGUL}}{t_1 + t_2} \quad (\text{eq. 3})$$

or

$$V_{ton} \cdot \frac{t_1 + t_2}{T} = V_{REGUL}$$

Given the low regulation bandwidth of the PFC systems, ($V_{CONTROL}$) and then (V_{REGUL}) are slow varying signals. Hence, the ($V_{ton} \cdot (t_1 + t_2) / T$) term is substantially constant. Provided that in addition, (t_1) is proportional to (V_{ton}), Equation 1 leads to: ($I_{in} = k \cdot V_{in}$), where k is a constant. More exactly:

$$I_{in} = k \cdot V_{in}$$

$$\text{where : } k = \text{constant} = \left[\frac{1}{2L} \cdot \frac{V_{REGUL}}{(V_{REGUL})_{max}} \cdot t_{on,max} \right]$$

Where $t_{on,max}$ is the maximum on-time obtained when V_{REGUL} is at its ($V_{REGUL})_{max}$ maximum level. The

Where $T = (t_1 + t_2 + t_3)$ is the switching period and V_{in} is the ac line rectified voltage.

In light of this equation, we immediately note that I_{in} is proportional to V_{in} if $[t_1 (t_1 + t_2) / T]$ is a constant.

parametric table shows that $t_{on,max}$ is equal to 25 μs ($T_{ON(LL)}$) at low line and to 8.3 μs ($T_{ON(HL)}$) at high line (when pin2 happens to exceed 2.2 V with a pace higher than 40 Hz – see BO 25 ms blanking time).

The input current is then proportional to the input voltage. Hence, the ac line current is properly shaped.

One can note that this analysis is also valid in the CrM case. This condition is just a particular case of this functioning where ($t_3=0$), which leads to ($t_1+t_2=T$) and ($V_{TON}=V_{REGUL}$). That is why the NCP1611 automatically adapts to the conditions and transitions from DCM and CrM (and vice versa) without power factor degradation and without discontinuity in the power delivery.

Hence, we can re-write the above equation as follows:

$$I_{in} = \frac{V_{in} \cdot T_{ON(LL)}}{2 \cdot L} \cdot \frac{V_{REGUL}}{(V_{REGUL})_{max}}$$

at low line.

$$I_{in} = \frac{V_{in} \cdot T_{ON(HL)}}{2 \cdot L} \cdot \frac{V_{REGUL}}{(V_{REGUL})_{max}}$$

at high line.

From these equations, we can deduce the expression of the average input power:

$$P_{in,avg} = \frac{(V_{in,rms})^2 \cdot V_{REGUL} \cdot T_{ON(LL)}}{2 \cdot L \cdot (V_{REGUL})_{max}}$$

at low line

$$P_{in,avg} = \frac{(V_{in,rms})^2 \cdot V_{REGUL} \cdot T_{ON(HL)}}{2 \cdot L \cdot (V_{REGUL})_{max}}$$

at high line

Where ($V_{REGUL})_{max}$ is the 1 V V_{REGUL} maximum value.

Hence, the maximum power that can be delivered by the PFC stage is:

$$(P_{in,avg})_{max} = \frac{(V_{in,rms})^2 \cdot T_{ON(LL)}}{2 \cdot L}$$

at low line

$$(P_{in,avg})_{max} = \frac{(V_{in,rms})^2 \cdot T_{ON(HL)}}{2 \cdot L}$$

at high line

Figure 65. PWM circuit and timing diagram.

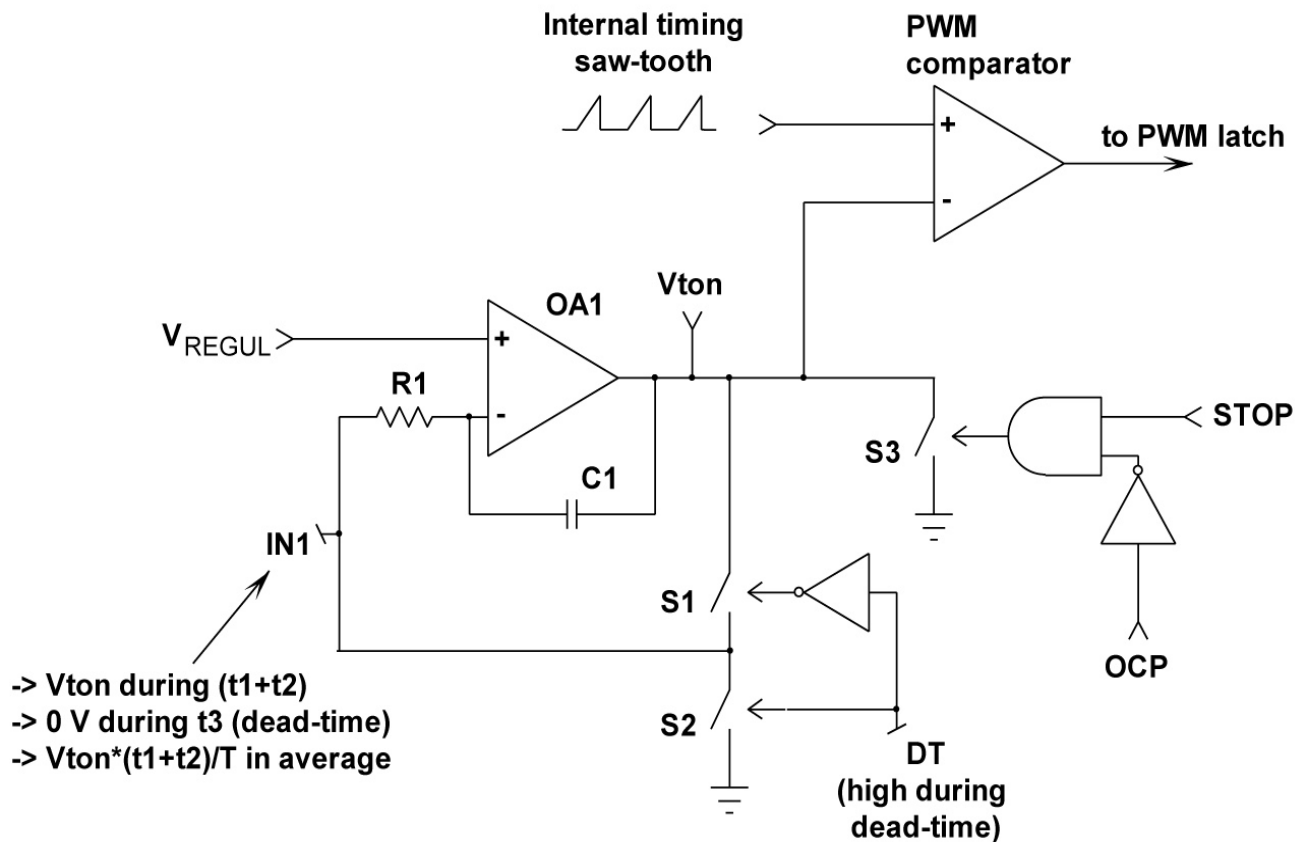

Figure 66. V_{TON} Processing Circuit. The integrator OA1 amplifies the error between V_{REGUL} and IN1 so that on average, $(V_{TON} * (t_1+t_2)/T)$ equates V_{REGUL} .

Remark:

The “ V_{ton} processing circuit” is “informed” when a condition possibly leading to a long interruption of the drive activity (functions generating the STOP signal that disables the drive – see block diagram – except OCP, i.e., OVP, OverStress, SKIP, staticOVP and OFF). Otherwise, such situations would be viewed as a normal dead-time phase and V_{ton} would inappropriately over-dimension V_{ton} to compensate it. Instead, as illustrated in Figure 66, the V_{ton} signal is grounded leading to a short soft-start when the circuit recovers.

Regulation Block and Output Voltage Control

A trans-conductance error amplifier (OTA) with access to the inverting input and output is provided. It features a typical trans-conductance gain of 200 μS and a maximum capability of $\pm 20 \mu A$. The output voltage of the PFC stage is typically scaled down by a resistors divider and monitored by the inverting input (pin 8). Bias current is minimized (less than 500 nA) to allow the use of a high impedance feed-back network. However, it is high enough so that the pin remains in low state if the pin is not connected.

The output of the error amplifier is brought to pin 1 for external loop compensation. Typically a type 2 network is applied between pin1 and ground, to set the regulation bandwidth below about 20 Hz and to provide a decent phase boost.

The swing of the error amplifier output is limited within an accurate range:

- It is forced above a voltage drop (V_F) by some circuitry.

- It is clamped not to exceed $4.0\text{ V} + \text{the same } V_F$ voltage drop.

Hence, V_{pin1} features a 4 V voltage swing. V_{pin1} is then offset down by (V_F) and scaled down by a resistors divider before it connects to the “ V_{TON} processing block” and the PWM section. Finally, the output of the regulation block is a signal (“ V_{REGUL} ” of the block diagram) that varies between 0 and a top value corresponding to the maximum on-time.

The V_F value is 0.5 V typically.

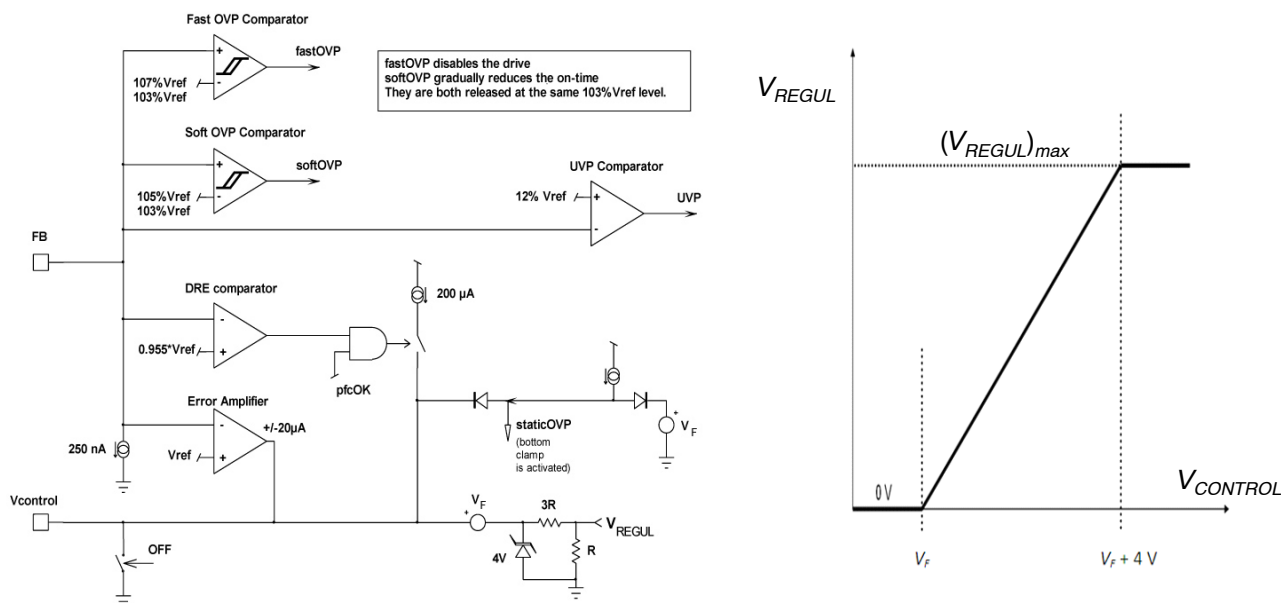

Figure 67. a) Regulation Block Figure (left), b) Correspondence Between V_{CONTROL} and V_{REGUL} (right)

Given the low bandwidth of the regulation loop, abrupt variations of the load, may result in excessive over or under-shoot. Over-shoot is limited by the Over-Voltage Protection connected to pin 8.

The NCP1611 embeds a “*dynamic response enhancer*” circuitry (DRE) that contains under-shoots. An internal comparator monitors the feed-back (V_{pin8}) and when V_{pin8} is lower than 95.5% of its nominal value, it connects a 200 μ A current source to speed-up the charge of the compensation network. Effectively this appears as a 10x increase in the loop gain.

In A version, DRE is disabled during the start-up sequence until the PFC stage has stabilized (that is when the “pfcOK” signal of the block diagram, is high). The resulting slow and gradual charge of the pin1 voltage ($V_{CONTROL}$) softens the soft start-up sequence. In B version, DRE is enabled during start-up to speed-up this phase and allow for the use of smaller V_{CC} capacitors.

The circuit also detects overshoot and immediately reduces the power delivery when the output voltage exceeds 105% of its desired level. The NCP1611 does not abruptly interrupt the switching. Instead, the signal V_{TON} that controls the on-time is gradually decreased by grounding

the V_{REGUL} signal applied to the V_{TON} processing block (see Figure 66). Doing so, the on-time smoothly decays to zero in four to five switching periods typically. If the output voltage still increases, a second comparator immediately disables the driver if the output voltage exceeds 107% of its desired level.

The error amplifier OTA and the OVP, UVP and DRE comparators share the same input information. Based on the typical value of their parameters and if ($V_{out,nom}$) is the output voltage nominal value (e.g., 390 V), we can deduce:

- Output Regulation Level: $V_{out, nom}$
- Output UVP Level: $V_{out, uvp} = 12\% \times V_{out, nom}$
- Output DRE Level: $V_{out, dre} = 95.5\% \times V_{out, nom}$
- Output Soft OVP Level: $V_{out, sovp} = 105\% \times V_{out, nom}$
- Output Fast OVP level: $V_{out, fovp} = 107\% \times V_{out, nom}$

Current Sense and Zero Current Detection

The NCP1611 is designed to monitor the current flowing through the power switch. A current sense resistor (R_{sense}) is inserted between the MOSFET source and ground to generate a positive voltage proportional to the MOSFET current (V_{CS}). The V_{CS} voltage is compared to a 500 mV internally reference. When V_{CS} exceeds this threshold, the

OCP signal turns high to reset the PWM latch and forces the driver low. A 200 ns blanking time prevents the OCP comparator from tripping because of the switching spikes that occur when the MOSFET turns on.

The CS pin is also designed to receive a signal from an auxiliary winding for Zero Current Detection. As illustrated in Figure TBD, an internal ZCD comparator monitors the pin4 voltage and if this voltage exceeds 750 mV, a demagnetization phase is detected (signal ZCD is high). The auxiliary winding voltage is applied through a diode to prevent this signal from distorting the current sense information during the on-time. Thus, the OCP protection is not impacted by the ZCD sensing circuitry. This comparator incorporates a 500 mV hysteresis and is able to detect ZCD pulses longer than 200 ns. When pin4 voltage drops below the lower ZCD threshold, the driver can turn high within 200 ns.

It may happen that the MOSFET turns on while a huge current flows through the inductor. As an example such a situation can occur at start-up when large in-rush currents charge the bulk capacitor to the line peak voltage. Traditionally, a bypass diode is generally placed between the

input and output high-voltage rails to divert this inrush current. If this diode is accidentally shorted, the MOSFET will also see a high current when it turns on. In both cases, the current can be large enough to trigger the ZCD comparator. An AND gate detects that this event occurs while the drive signal is high. In this case, the “OverStress” signal goes high and disables the driver for an 800 μ s delay. This long delay leads to a very low duty-ratio operation in case of “OverStress” fault in order to limit the risk of overheating.

When no signal is received that triggers the ZCD comparator during the off-time, an internal 200- μ s watchdog timer initiates the next drive pulse. At the end of this delay, the circuit senses the CS/ZCD pin impedance to detect a possible grounding of this pin and prevent operation. The CS/ZCD external components must be selected to avoid false fault detection. 3.9 k Ω is the recommended minimum impedance to be applied to the CS/ZCD pin when considering the NCP1611 parameters tolerance over the -40°C to 125°C temperature range. **Practically, R_{CS} must be higher than 3.9 k Ω in the application of Figure 68.**

Figure 68. Current Sense and Zero Current Detection Blocks

Brown-Out Detection

The V_{SENSE} pin (pin2) receives a portion of the instantaneous input voltage (V_{in}). As V_{in} is a rectified sinusoid, the monitored signal varies between zero or a small voltage and a peak value.

For the brown-out block, we need to ensure that the line magnitude is high enough for operation. This is done as follows:

- The V_{SENSE} pin voltage is compared to a 1 V reference.
- If V_{pin2} exceeds 1 V, the input voltage is considered sufficient
- If V_{pin2} remains below 0.9 V for 50 ms, the circuit detects a brown-out situation (100 mV hysteresis).

By default, when the circuit starts operation, the circuit is in a fault state (“BO_NOK” high) until V_{pin2} exceeds 1 V.

When “BO_NOK” is high, the drive is not disabled. Instead, a 50 μ A current source is applied to pin 1 to gradually reduce $V_{CONTROL}$. As a result, the circuit only stops pulsing when the staticOVP function is activated (that is when $V_{CONTROL}$ reaches the skip detection threshold). At that moment, the circuit turns off (see Figure 2). This method limits any risk of false triggering. The input of the PFC stage has some impedance that leads to some sag of the input voltage when the input current is large. If the PFC stage suddenly stops while a high current is drawn from the mains, the abrupt decay of the current may make the input voltage rise and the circuit detect a correct line level. Instead, the

gradual decrease of V_{CONTROL} avoids a line current discontinuity and limits the risk of false triggering.

Pin2 is also used to sense the line for feed-forward. A similar method is used:

- The V_{SENSE} pin voltage is compared to a 2.2 V reference.
- If V_{pin2} exceeds 2.2 V, the circuit detects a high-line condition and the loop gain is divided by three (the internal PWM ramp slope is three times steeper)

- Once this occurs, if V_{pin2} remains below 1.7 V for 25 ms, the circuit detects a low-line situation (500 mV hysteresis).

At startup, the circuit is in low-line state (“LLine” high) until V_{pin2} exceeds 2.2 V.

The line range detection circuit allows more optimal loop gain control for universal (wide input mains) applications.

As portrayed in Figure 69, the pin 2 voltage is also utilized to generate the current information required for the frequency fold-back function.

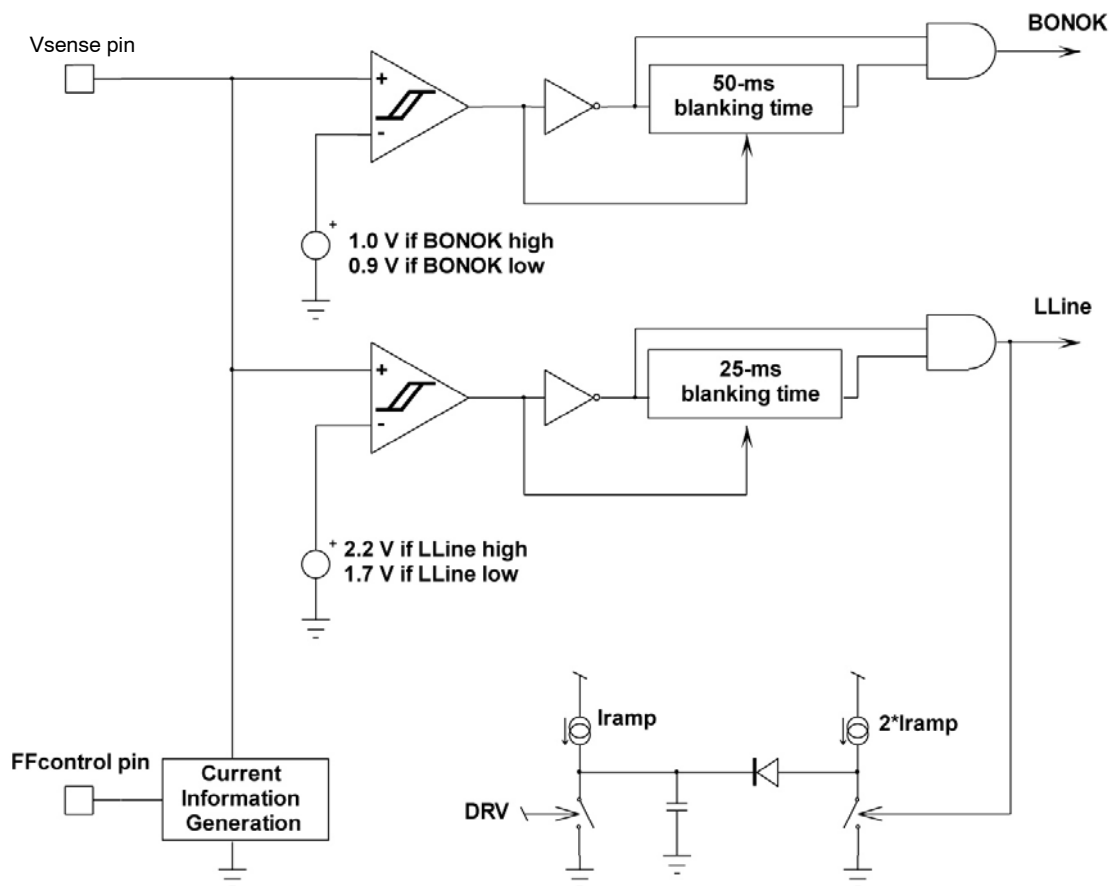

Figure 69. Input Line Sense Monitoring

Thermal Shutdown (TSD)

An internal thermal circuitry disables the circuit gate drive and keeps the power switch off when the junction temperature exceeds 150°C. The output stage is then enabled once the temperature drops below about 100°C (50°C hysteresis).

The temperature shutdown remains active as long as the circuit is not reset, that is, as long as V_{CC} is higher than $V_{\text{CC(RESET)}}$. The reset action forces the TSD threshold to be the upper one (150°C), thus ensuring that any cold start-up will be done with the proper TSD level.

Output Drive Section

The output stage contains a totem pole optimized to minimize the cross conduction current during high frequency operation. The gate drive is kept in a sinking mode whenever the Under-Voltage Lockout is active or more generally whenever the circuit is off (i.e., when the “Fault Latch” of the block diagram is high). Its high current capability (–500 mA/+800 mA) allows it to effectively drive high gate charge power MOSFET. As the circuit exhibits a large V_{CC} range (up to 35 V), the drive pin voltage

is clamped not to provide the MOSFET gate with more than 14 V.

Reference Section

The circuit features an accurate internal 2.5 V reference voltage (V_{REF}) optimized to be $\pm 2.4\%$ accurate over the temperature range.

OFF Mode

As previously mentioned, the circuit turns off when one of the following faults is detected:

- Incorrect feeding of the circuit (“UVLO” high when $V_{CC} < V_{CC(off)}$, $V_{CC(off)}$ equating 9 V typically).
- Excessive die temperature detected by the thermal shutdown.
- Under-Voltage Protection.
- Brown-Out Fault and static OVP (see block diagram)

Generally speaking, the circuit turns off when the conditions are not proper for desired operation. In this mode, the controller stops operating. The major part of the circuit sleeps and its consumption is minimized.

More specifically, when the circuit is in OFF state:

- The drive output is kept low
- All the blocks are off except:
 - The UVLO circuitry that keeps monitoring the V_{CC} voltage and controlling the start-up current source accordingly.
 - The TSD (thermal shutdown)
 - The Under-Voltage Protection (“UVP”).
 - The brown-out circuitry
- $V_{CONTROL}$ is grounded so that when the fault is removed, the device starts-up under the soft start mode (B Version).
- The internal “pfcOK” signal is grounded.
- The output of the “ V_{TON} processing block” is grounded

Failure detection

When manufacturing a power supply, elements can be accidentally shorted or improperly soldered. Such failures can also happen to occur later on because of the components fatigue or excessive stress, soldering defaults or external interactions. In particular, adjacent pins of controllers can be shorted, a pin can be grounded or badly connected. Such open/short situations are generally required not to cause fire,

smoke nor big noise. The NCP1611 integrates functions that ease meet this requirement. Among them, we can list:

- Floating feedback pin
A 250 nA sink current source pulls down the voltage on the feedback pin if it is floating so that the UVP protection trips and prevents the circuit from operating. This current source is small (450 nA maximum) so that its impact on the bulk voltage regulation level remains negligible with typical feedback resistor dividers.
- Fault of the GND connection
If the GND pin is properly connected, the supply current drawn from the positive terminal of the V_{CC} capacitor, flows out of the GND pin to return to the negative terminal of the V_{CC} capacitor. If the GND pin is not connected, the circuit ESD diodes offer another return path. The accidental non connection of the GND pin can hence be detected by detecting that one of this ESD diode is conducting. Practically, the CS/ZCD ESD diode is monitored. If such a fault is detected for 200 μ s, the circuit stops operating.
- Detection the CS/ZCD pin improper connection
The CS/ZCD pin sources a 1 μ A current to pull up the pin voltage and hence disable the part when the pin is floating. If the CS/ZCD pin is grounded, the circuit cannot monitor the ZCD signal and the 200 μ s watchdog timer is activated. When the watchdog time has elapsed, the circuit sources a 250 μ A current source to pull-up the CS/ZCD pin voltage. No drive pulse is initiated until the CS/ZCD pin voltage exceeds the ZCD 0.75 V threshold. Hence, if the pin is grounded, the circuit stops operating. Circuit proper operation requires the pin impedance to be 3.9 k Ω or more, the tolerance of the NCP1611 impedance testing function being considered over the -40°C to 125°C temperature range.
- Boost or bypass diode short
The NCP1611 addresses the short situations of the boost and bypass diodes (a bypass diode is generally placed between the input and output high-voltage rails to divert this inrush current). Practically, the overstress protection is implemented to detect such conditions and forces a low duty-cycle operation until the fault is gone.

Данный компонент на территории Российской Федерации

Вы можете приобрести в компании MosChip.

Для оперативного оформления запроса Вам необходимо перейти по данной ссылке:

<http://moschip.ru/get-element>

Вы можете разместить у нас заказ для любого Вашего проекта, будь то серийное производство или разработка единичного прибора.

В нашем ассортименте представлены ведущие мировые производители активных и пассивных электронных компонентов.

Нашей специализацией является поставка электронной компонентной базы двойного назначения, продукции таких производителей как XILINX, Intel (ex.ALTERA), Vicor, Microchip, Texas Instruments, Analog Devices, Mini-Circuits, Amphenol, Glenair.

Сотрудничество с глобальными дистрибьюторами электронных компонентов, предоставляет возможность заказывать и получать с международных складов практически любой перечень компонентов в оптимальные для Вас сроки.

На всех этапах разработки и производства наши партнеры могут получить квалифицированную поддержку опытных инженеров.

Система менеджмента качества компании отвечает требованиям в соответствии с ГОСТ Р ИСО 9001, ГОСТ РВ 0015-002 и ЭС РД 009
